TITLE: The Production of Two-layer Soldered Tubes (Proizvodstvo

dvusloynykh payanykh trub)

PERIODICAL: Stal', 1958, Nr 8, pp 722 - 726 (USSR)

ABSTRACT: The process of production of two-layer soldered tubes was developed by TsNIIChk and tested on the Sinarskiy Pipe Plant, The tubes are made from a cold-rolled steel strip coated on both sides with a thin layer of copper. The edges of the strip are bevelled and the strip is formed into a twolayer tube semis with a close contact of the layers and overlapping of edges (Figure 1). The tube semis are passed through an electric furnace, heated to a temperature somewhat higher than the melting temperature of copper. The heating and cooling is done in a protective atmosphere. During the heating, soldering of the layers along the whole contact surface takes place. Thus, the manufacturing process consists of four main operations: copper coating of strip, bevel cutting of edges, forming of strip into tube semis and soldering. This kind of tube is being produced within a range of diameters from 6 to 16 mm with

Card1/4

The Production of Two-layer Soldered Tubes

SOV/133-58-8-13/30

the wall thicknesses from 0.6 to 0.9 mm. Low-carbon, mild steel (08) cold-rolled strip, 0.3 - 0.45 mm in thickness supplied in an annealed state in coils of a width corresponding to the required diameter of the tubes is used as a starting material. The strip is electrolytically coated with copper to a thickness of 4µ; 1 µ of copper is deposited from the cyanide electrolyte and 3 µ from an acid electrolyte. The coating process is continuous (Figure 2, table). The speed of strip through the electrolytic baths varies from 2.85 to 9.65 m/min, depending on its width. Cutting of edges is done in one pass without liquid cooling of knives. The rate of cutting up to 65 m/min (Figures 3 and 4). Forming of strip according to scheme shown in Figure 5 is done on a continuous 14-stand mill (Figure 6) produced by TeKBMM TeNIITMASh at a rate of 30-45 m/min. Formed semis are cut into a mensured length (14 100 mm). Lots of 30 semis are passed for soldering in an electric resistance furnace (Figure 7) consisting of two chambers: heating and cooling. The temperature of the heating chamber is maintained at 1130 - 1140 C. The rate of

Card2/4

The Production of Two-layer Soldered Tubes SOV/133-58-8-13/30

passage through the furnace varies from 0.78 to 2.0 m/min, depending on the tute diameter. Protective atmosphere is obtained from charcoal yas producer (CO 31-37%, H<sub>2</sub>>11%, CH<sub>4</sub> 0.2-0.7%, CO<sub>2</sub> 1-4%, humidity 7-10 g/m<sup>3</sup>). In order to retain a uniform distribution of copper on the surface of tubes during soldering, the latter are coated with a thin layer of a special coating material (not specified) before soldering. It is stated that the mechanical properties of tubes are similar to those of seamless tubes from mild steel (tensile strength 38-42 kg/mm<sup>2</sup>, relative elongation 24-30% and pass the hydraulic test according to GOST 301-50). It is pointed out that the process of production of the above tubes is already introduced into practice. It presents significant, technical and economic dvantages in comparison with the drawing process. Such tubes can replace

Card3/4

The Production of Two-layer Soldered Tubes SO

SOV/133-58-8-13/30

successfully steel seamless tubes as well as copper and brass tubes, thus providing a large saving of non-ferrous metals.

# METHODS OF SPEEDING-UP THE OPERATION OF DIGITAL COMPUTERS

I. Y. AKUSHSKY, L. B. YEMSLYANOV-YAROSLAVSKIY, S. A. KLIYANKO, V. S. LINBRY, G. D. MOMARHOV Institute for Scientific Research of Electonic

Mathematical Machines, Moscow, USSR.

In the paper are considered different methods of speeding-up operations in digital computers.

Methods of accelerating the digit by digit multiplication by overlapping in time the operations of addition and shift; the method of the "travelling wave" when the addition of several partial products is effected simultaneously, etc.

For speeding-up the division operation a method is recommended by which the information contained in the code of the next remainder is used for determining in one sten the group of the quotient consecutive digits.

Are considered the advantages, from the point of view of operation speeding-up, of storage of codes in not normalised condition and representation of negative numbers in the machine in reverse code (with introduction of code feature). Combined methods of calculation of certain algebraic expressions in the conditions of an arithmetic device with an increased number of components.

Methods are described for speeding-up the addition elementary operation, which ensure single-shot operation of each component of the add circuit, as well as the methods of speeding up the group shift by means of a special shifter designed in the form of a

Considerations are given on the expediency of including the calculations of the values of elementary functions in the list of main machine operations, and some algorithms are given (which are adaptable for their circuit execution by the arithmetic device), on Paper presented at Intl. Conf. on Information Processing, UNESCO House, Paris, 15-20 Jul 50

THE PROPERTY OF THE PROPERTY O

THE RESERVE OF THE PROPERTY OF

The role of microprogram control for accelerating operations is discussed. In particular, at microprogram control, when a single-sided high-speed large caracity memory is used, it seems possible to obtain efficient results by calculating the elementary function values on the basis of block-poly-nomial approximation of functions by different polynomials at various intervals.

SOURCE: Byulleten' isobreteniy i tovarných snakov, no. 18, 1965, 93

TOPIC TAGS: digital computer, computer technique, computer system, computer switching, computer programming, computer control

ABSTRACT: This Author Certificate presents a method for accomplishing transitions to subprograms at an arbitrary point of the basic program in digital computers. It is designed to increase the control effectiveness of the machine with simultaneous economy of equipment. A signal is shaped with the help of an apparatus which accomplishes the stop based on the address in the control panel (command address, number address, index-list). This signal, via operation mode switches ("stop", "shift", "terminate"), is fed to circuits controlling the shifting Card 1/2

: Ignition voltage of discharge in He, Ni, Ar, Kr, and Xe at low Periodical

: Zhur. tekh. fiz., 25, No 6 (June), 1955, 1038-1044

Abstract

The authors investigate the left branches of the Paschen curves in the inert gases He, Me, Ar, Kr, and Xe up to values of ignition voltage equal to 40-45 kilovolts. The material of the cathode and anode are nickel and graphite. They consider the influence of various elementary processes upon the position and shape of the curves of ignition. They confirm experimentally the earlier expressed assumption concerning the essential role of the material of the anode. Conclusions: Rather stable values of ignition voltages of discharge are obtained on cold nickel cathode subjected ("trained") by high voltage; prolonged tempering of the cathode in vacuuo at 800°C does not noticeably change these values. Ignition curves in homogeneous field for Ar, Kr, and Xe almost coincide; Ne and especially He possess considerably higher ignition voltages. Discharge ignition voltages in inert gases are greater for graphite cathode than for nickel cathode. Substitution of nickel by graphite as anode material increases ignition voltages more than a similar

substitution of cathode material, the cause for this being the decrease in number of ionizations by electron collisions occurring in Institution:

Title

: Characteristics of probes at positive potentials and measurement of density

Periodical

: Zhur. tekh. fiz., 25, No 9 (September), 1955, 1581-1596

Abstract

The authors review the discharge phenomena near a probe that has a positive potential relative to the plasma. Utilization of certain properties of the volt-ampere characteristics of such a probe permit them to measure the variation of the gas density under the action of discharge fed by a direct or alternating current. They find that with increasing positive potential on the probe relative to gas-discharge plasma the volt-ampere characteristics of the probe indicate the existence of two regimes: a) regime of probe corresponding to non-independent form of discharge, and b) regime of anode corresponding to independent discharge able to exist even when the main discharge is switched off; the transition between the two regimes of probe operation is effected in most cases by a jump suggestive of the phenomenon of rupture. Difference in potentials between plasma and positively charged probe at which rupture of layer near probe occurs increases with decrease in the density of the gas and with increase in density of discharge current; these properties can be used to measure the gas density in the limits of intense discharge, and suggests a convenient method for measuring

FD-3133

A A A CONTROL OF THE PROPERTY OF THE PROPERTY

densities in various gases and vapors. The region of measurements of gas densities can be regulated by changes in the radius of the cylindrical probe used, since the rupture strength of the layer increases with decrease in radius; this is the result of decrease in the thickness of that part of the layer near the probe in which the electrons produce intense ionization of the gas. Comparatively small increase in probe current in the positive branch of the characteristics of a plane probe is mainly determined by increase in plasma of ions generated in the layer; recharging of positive ions amplifies this effect by several times. Transition of the probe to. the anode regime is accompanied by formation around the probe of a new intense plasma of small size separated from the remaining plasma by a potential drop. Ordinarily this regime is unstable and the probe passes continuously from the anode regime to the probe regime and reversely, thus forming deep oscillations in the voltage strength with frequency of 104 to 106 cycles. The proposed mechanism governing these oscillations consists in the periodic accumulation of positive ions around the probe with formation of new small plasma and in the disintegration of this plasma after the voltage at the probe drops to a small value. For the study of dynamic variation of gas density in discharges the authors developed an impulse probe method permitting measurement of instantaneous values of gas density in various phases of discharge burning on alternating or reviodic current. KLJARFELID, B.H., FRID, A.A.

A Filamentlike Anode in a Gas Discharge. Zurn. techn.fls, 26, fasc. 11, 2541-2547 (1956)

Issued: 12 / 1956

Here the experimental investigation of the ignition mechanism of the discharge in a long discharge tube along the axis of which a thin wire is drawn, is described. The application of a potential, which is positive with respect to the cathode, to the filament causes a discharge luminescence on the surface of the filament as well as the instant ignition of the discharge between the main electrodes. In mercury vapors (p = 0,001 mm torr in the case of discharge

currents of the order from 10-5 to 10-3 ampères on the filament) a weak luminescence extends over the surface of the filament to the extent of up to 75 cm. However, a reliable discharge is attained only if the discharge tube is not very long. That portion of the filament which is next to the cathode is the anode of the independent discharge. The remaining part of the filament collects the electrons which are propagated from the domain of the independent discharge. These electrons penetrate into the cylindrical field between the walls of the tube and the field, describe several circles round the filament, and then impinge upon the filament. Near the filament the electrons have the highest kinetic energy and ionise the gas intensely. On this occasion a noticeable concentration of electrons and positive ions is brought about in

ABSTRACT:

The newly constructed discharge tube was available in two shapes: in one case the electrodes were firmly mounted, and in the other the distance between them could be varied from 4 to 32 cm by moving one of the electrodes. The nickel electrodes had a diameter of 80 mm, so that the field forming between the electrodes was sufficiently homogeneous.

Before being used the polished electrodes were hardened in the vacuum by high frequency hardening.

The hydrogen pressure was regulated by means of the heating of titanium hydride which was embedded in the discharge tube. The well smoothed high voltage was supplied by a rectifier and could be regulated without steps from 0 - 40 kV. The high-voltage form of discharge which forms in the left part of the Paschen curve after ignition is distinguished by the fact that the voltage loss on the electrodes is independent of amperage. In particular,

AUTHORS: Klyarfel'd, B. N. , Neretina, N. A. 57-2-18/32 TITLE: The Anode Region in Gas Discharge at Low Pressures (Anodnaya oblast! v Gazovom razryade pri mizkikh davleniyakh) I. The Influence of the Anode Hold on the Sign and the Quantity of the Anode Fall (I. Vliyaniye formy anoda na znak i velichinu anodnogo padeniya) PERIODICAL: Zhurnal Tekhnicheskoy Fiziki, 1958, Vol. 28, Nr 2, pp.296-315 ABSTRACT: The phenomena at the anode in nercury discharge were here investigated for the 3 most characteristic cases: a hollow cylindrical anode, a semispherical anode with a diameter equal to 0,3 of the column diameter and a flat anode filling the entire column cross section. The investigations were performed at pressures of below 0,1 nn torr. (i.e. in the absence of a marked discharge concentration in the column or at the anode) and in the range of discharge-currents from 0,03-10 A, at a column diameter of 32 nm. Tie hollow and semi\_spherical Card 1/4 anode in all cases possess a negative and positive sign of

the anode fall respectively. A heating of these anodes to 700-800°C does not cause a charge of the quantity or the sign of the anode fall. Summarizing the authors state: 1) The sign of the anode fall is determined by the conditions for a generation and for the disappearance of the positive ions in the region of the anode. In those cases where these conditions favor the formation of the concentration of positive ions which are sufficient for the neutralization of the space charge of the electrons transferring the discharge-current to the anode, no anode fall occurs or it has a small negative value. In the case of a deficiency of positive ions a positive anode fall forms. 2) An anode of small dimensions near which the positive ions are dispersed under the simultaneous influence of the diffusion and the electric field is in all cases characterized by the positive anode fall of considerable amount and by the development of supersonic frequency--variations in the anode region. The hollow anode which is filled with positive anodes of long life is characterized by a negative anode fall up to mercury-vapor-pressures of 0.1 am (higher up the contraction of the discharge begins). 3) The

THE STATE OF THE PARTY OF THE P

The Anode Region in Gas Discharge at Low Prossures. I. The Influence of the Anode Mold on the Sign and the Quantity of the Anode Foll

flat front-anode which fills the entire cross section of the discharge is characterized by a negative anode fall at pressures up to 0,01 mm and by a positive amode fall at p > 0.01 mm. In the latter case the anois fall only remains constant in discharge-currents of below 1 A (diameter of the tube . - 32 mm). The reason for the change of sign of the anode fall on a rise of pressure lies in the deterioration of the cenditions for the retention of the high concentration of positive ions. In a cold state the flat anode mainly has a negative anode fall. 4) The investigation of the space in front of the flat front-anode by means of probes showed that the selection of the lonic currents directed toward the anode through the anode creates a zone with diminished concentration of charged particles and diminished brightness. In the presence of a nedative anode full in the section of the positive column lying against the anode a flat concentration-maximum of the charged particled occurs on a length of 4 - 5 alumn diameter. In a positive anode fall the disturbance of the honogeneity of the column bogins in a distance from the anote with an order of

Card 3.4

The Anode Region in Cas Discherge at Law Pressures. I. The Influence of the Anode Mold on the Sign and the quantity of the Anode Foll

magnitude beginning from one columnitanter . 5) The analysis of the phenomena in the regetive erois fall shows that the quantity of the ancde fall inprouses with the increase in the electron-temperature and with the increase in the relation of the density of the random ionic current to the density of the discharge-current. Both conditions are satisfied in the place ma of a discharge between an annualed thread emitting electrons and a coaxial cylindrical anode. In a number of inert gases it was found that in a similar kind of discharge under pressure of the order of sagnitude 10-4 - 10-3 mm the electron-tenperature-values attain 150-200 COO'K, whereas the relation of the densities of the disordered ionic current and the discharge--current is squal to several decens. The negative anode falls measured according to the nothed of probes on that occasion attained 40-50 V. There are 14 figures, 2 tables, and 20 references, 11 of which are Slavic.

TITLE:

Formation of Light Spots on the Anode

PERIODICAL: Radiotekhnika i elektronika, 1959, Vol 4, Nr 8,

pp 1301 - 1305 (USSR)

ABSTRACT:

When the positive anode fall U and the gas pressure reach pertain values, it is found that bright light spots are formed on the uniform layer of the anode glow. It has been found that in mercury-vapour discharges, these values are U = 7-8 V, p = 0.003 mm Hg. When the spot

is formed, the anode voltage fall changes discontinuously and is reduced to 2 - 4 V. When the pressure is further increased, the spot is reduced and a number of new spots appear; these form regular patterns on the surface of the anode. In spite of extensive experimental data on the anole spots, their nature is not as yet understood. The authors investigated the properties of the plasma inside the individual anode spots. This was done by employing a small probe which could be introduced into a spot through

Card1/4

66695

Formation of Light Spots on the Anode

a narrow slot cut in the anode. Figure 1 shows the change U of the voltage fall on a discharge and the change of the positive potential fall AU of the anode as a function of the current in the anode region. The figure shows that the formation of the spot leads to the breakdown of the layer of the negative space charge in the vicinity of a given section of the anode. The values of the discharge current and the gas pressure at which the spots appeared were investigated for a hydrogen discharge produced on a flat anode. The diameter of the experimental tube was 50 mm. The results of the measurements are shown in Figure 2. The numbers by the various curves denote the number of spots. It was found that the spots appear only within a definite region of pressures. At comparatively high pressures, the spots become blurred and finally disappear. The pressure at which the spots exist are as follows: 0.003 to 1 mm for mercury; 0.15 to 5 mm for hydrogen and a few mm to about 200 mm for neon and helium. The mechanism of the spot formation can be explained as

follows. Under the conditions leading to the increase of the anode fall and at a sufficiently high pressure, the density of the ion generation is so high that a new plasma in the form of a fine film is formed near the surface of the anode. The existence of the plasma film is unstable. Probe measurements have shown that the potential inside the spots is a few volts higher than the anode potential. By employing a cathode oscillograph, it was found that intense oscillations with ultrasonic frequencies were produced in the double layer situated between the postive column and the spot. On the other hand, the oscillations in the ionic layer between the spot and the anode surface are comparatively weak. When the anode dimensions are small and the gas pressures are low, the anode is fully enveloped by the spot which then has the form of a glowing sphere. In this case, oscillations having a comparatively high amplitude and a frequency in the ultrasonic range are obtained at the anode. An approximate potential distribution in the vicinity of the anode during the various stages of the oscillation is,

TITLE:

The Anode Region in Low Pressure Gaseous Discharge: Part III. The Appearance of Supplementary Plasmas on the Anode (Anode Spots) ((I) ZhTF, XXVIII, 296, 1958; (II) ZhTF, XXIX, 15, 1959)

PERIODICAL:

Zhurnal tekhnicheskoy fiziki, 1960, Vol 30, Nr 2, pp 186-198 (USSR)

ABSTRACT:

For a positive anode voltage drop, the film of the discharge glow covers usually the anode uniformly. However, when the pressure exceeds a value characteristic for a given gas and the anode current density is kept above 10<sup>-3</sup> to 10<sup>-2</sup> a/cm<sup>2</sup>, a bright hemispherical spot is formed over the background of the anode glow. With

the further increase of pressure there is an increase in number of spots and their relative brightness while the radius of a single spot decreases. For particular values of pressure and current many sharply outlined

Discharge. Part III. The Appearance of SOV/57-30-2-9/18
Supplementary Plasmas on the Anode (Anode Spots)

spots cover the anode with regular patterns. At still higher pressures these spots disappear again. The authors review various explanations for the appearance of these spots given by researchers during last 35 years and conclude that the final answer about the nature of these spots is still far away. In the present paper they present investigations in vapors of mercury, in inert gases, and in hydrogen. Introducing probes into the spots from the anode side they managed to investigate directly the properties of spots. The regular patterns of spots were explained by the inverse influence of each spot on the discharge region surrounding it. To investigate the conditions for occurrence of spots the authors performed tests on Hg vapor for various values of pressure p, anode voltage drop Ua, current 1, and the temperature of the anode Ta. Results are on Fig. 1. Single line curves are obtained in absence of spots; the double line with one spot present. The relationship between the pressure and the number of spots was found using hydrogen discharge which produces many and stable spots. Results are on Pig. 2.

that the current density on the anode decreases from the center toward outer boundary. The current density on a spot is at most twice as strong as one the rest of the anode. To investigate the spots themselves, the authors used an anode arrangement as on Fig. 4.  $A_1$  is the basic anode;  $A_2$  - its central region with separate connection;  $S_1$  - probe made of tungsten wire 0.1 mm in diameter, with a 0.4 mm sphere at its end, 1.5 mm in front of  $A_2$ .  $S_2$  was inside the positive column and served to determine the anode voltage drop. Table A contains the results obtained.  $A_1$  and  $A_2$  are currents on  $A_1$  and  $A_2$ , respectively.  $A_1$  is the potential drop between  $A_2$  and the spot  $A_2$  between the spot and  $A_2$ .  $A_1$  is the potential difference between  $A_2$  and  $A_3$

necessary to keep the spot on  $A_2$ .  $T_e$  and  $T_e$  are electron temperatures in the spot and column, respectively. The authors note the relative constancy of the  $T_e$  ratio. In connection with K these temperatures the authors discovered the cause of large influence of the spots on the general

discharge. To calculate K, the average ionization  $\mathbf{z}$ te per electron, they developed an equation

$$a = AB\rho_0 \left(\frac{8a}{8m_0}\right)^{\eta_0} U^{\eta_0} e^{-\frac{E_0}{B}} \left[ \frac{U}{(1+BU)^{1-1} - \frac{U+U_0}{1+BU}} \right]$$
 (2)

using approximation for the effective ionization curves given by Klyarfel'd (J. of Phys. USSR, 5, 155, 1941). Here  $U = \frac{kTe}{e}$ , and substituting the temperature values one finds that K in the spot is 50 times larger than the K in the positive column. This was verified experimentally by discovering that 10% of the total current originating on  $A_2$  (and the spot) was sufficient to destroy completely the positive anode potential drop due to the large ion production inside the spot. In addition, the authors concluded after performing appropriate tests that the degasing of the anode, the the electron reflection from the anode, and the decrease of inelastic energy losses with an increase of pressure

Supplementary Plasmas on the Anode (Anode Spots)

THE THE PERSON NAMED IN TH

cannot be the decisive factors for the occurrence of the spots. On the basis of all the above they propose the following mechanism: An initial large anode voltage drop and sufficiently high gas pressure are the simultaneous necessary conditions for a large density of positive ion generation. When this ion generation reaches some critical value, a new plasma starts to develop in the form of a thin uniform layer whose potential exceeds that of the anode for a few volts. This state is, nevertheless, unstable, and a small nonuniformity in ion leads to a process exemplified The authors further investigate the on Fig. 7. influence of single spots on their surroundings and the condition allowing the simultaneous existence of many spots. With an increase in pressure the radius of action of single spots decreases, allowing creation of new spots with identical properties with respect to the discharge and, therefore, spaced in a regular pattern. Still higher pressure reduces the size and thickness of the spots to the thickness

The Anode Region in Low Pressure Caseous
Discharge. Part III. The Appearance of SOV/57-30-2-9/18
Supplementary Plasmas on the Anode (Anode Spots)

of the anode glow until they finally disappear. The authors gave also a detailed analysis of processes happening between electrodes and the plasma in three basic situations: (I) when the electrode is more negative than the plasma, (II) when the electrode is more positive than the plasma, and (III) when around the electrode is formed a supplementary plasma (spot). They point out that often the discharge represents a self-oscillating system, and periodic transitions of electrodes, or parts of electrodes, from one basic situation to another leads to a generation of low frequency potential oscillations. The final discussions were based on data from the literature as well as on data obtained by the authors. TITLE:

Applicability of similarity law to ignition of a gas discharge in hydrogen

Custa ru nantokan

PERIODICAL

Zhurnal eksperimental'noy i teoreticheskcy fiziki. v. 42, no. 2, 1962, 427 - 429

TEXT: The ignition potential of a gas discharge depends in different ways on the pressure p and the gap length d. In fact, a departure from the similarity law has been found for hydrogen in the range where pd  $\langle (pd)_{min} \rangle$ .

Experiments showed that these departures were equal for nickel, copper, and stainless steel electrodes, and that they did not vanish even when the gas pressure in the discharge gap was increased. A similar deviation from the similarity law was also found for deuterium. Reference is made to an earlier paper by the authors (ZhETF, 32, 933, 1957) as well as to a paper by L. G. Guseva (Trudy VEI, 63, 1, 17, 1958). There are 1 figure and 5 references: 2 Soviet and 3 non-Soviet. The references to the Englishlanguage publications read as follows: G. W. McClure. J. V.N.; Ouseve, L.O. TITIE: On the nature of the positive current-voltage characteristic of a low pr sure electric discharge SOURCE: Zhurnal tekhnicheskoy fisiki, v.35, no.2, 1965, 306-311 TOPIC TAGS: gas discharge, glow discharge, plasma, low pressure discharge, helium, argon ABSTRACT: High voltage discharges in helium and arron between plane carbonized iron electrodes were investigated experimentally and the results for helium at 0.08 mm Hg with 8 cm electrode separation are presented graphically. At low currents the potential remained constant at 4.6 kV; but when the current resched a certain threshold the potential increased and plasma could be observed in the vicinity of the anode. With further increase of current the plasma layer became thicker and the potential continued to rise. This increase in potential is ascribed to the efspotive decrease in the length of the discharge gap as more of the interelectrode space becomes cocupied by essentially equipotential plasma. The thickness of the

AUTHOR: ORG: All-Union Electrotechnical Institute in V.I.Legia Moscow (Ysesoyusnyy trotekhnicheskiy institut) TITLE: 0100 discharge at low pressures and current densities up to 0.1 A/cm2 Sounck: Zhurnal tekhnicheskoy žisiki, v. 36, no. 4, 1966, 704-713 TOPIC TACS: glow discharge, hydrogen, nitrogen, neon, arron, gas discharge, plasses ABSTRACT: Current-voltage characteristics of glow discharges between plane parallel electrodes in H2, N2, Ne, and Ar have been measured at voltages from 0.3 to 30 KV, currents from 10-9 to 10 A, and values of the pd product (pressure times electrode distance) corresponding to the left-hand branch; the minimum, and a portion of the right-hand branch of the Paschen curve. The dismeter of the electrodes was always greater than the distance between them, and care was taken to assure purity of the gases and to avoid distortion of the curves due to thermal effects. The high ourrent discharges were pulsed, the data being recorded on the fall of the pulse. Measurements at intermediate currents by both the pulse and continuous techniques gave concordant results. Many of the recorded current-voltage characteristics are present graphically, and they are discussed at some length. Glow discharges are classified into three groups, for which there are proposed the following designations: Simple Card 1/2 UDC: 537,525 The Alexander Control 141 145 144

1 28485-66 ACC NR: AP6013126 (or Simplest) Glow Discharge; Dense Glow Discharge; and Mormal Glow Discharge. simple glow discharges comprise the Townsend discharge; which is thus regarded as a kind of glow discharge, and the high voltage discharge; they are characterized by absence of space charge between the electrodes and a potential that is independent of the current over a very wide range. The dense glow discharges are characterized by increase of the voltage with increasing current, decrease of the voltage (at constant current) with increasing value of the pd product, and the presence beyond the cathode fall region of plasma, the potential of which is close to that of the snode and which exhibits a typical negative glow, In the normal glow discharge the potential is almost independent of the value of the pd product, the current density at the cathode is nearly independent of the current (and not proportional to it as in the simple and dense glow discharges), and a negative glow plasma fills only part of the interelectrode region. As the current is increased at low pressures a simple glow discharge passes directly into a dense glow discharge; at higher pressures there is an intermediate range in which the glow discharge is normal. It is suggested that it may prove necessary to introduce further new terms to describe the still insufficiently investigated glow discharges for Values of the pd product exceeding 100 mm Hg x cm. V.V. Vlasov, A.Ye. Kulikov, and A.T. Pavlova participated in the experimental work, Orig, art, hast 7 figures. BUBM DATE:
